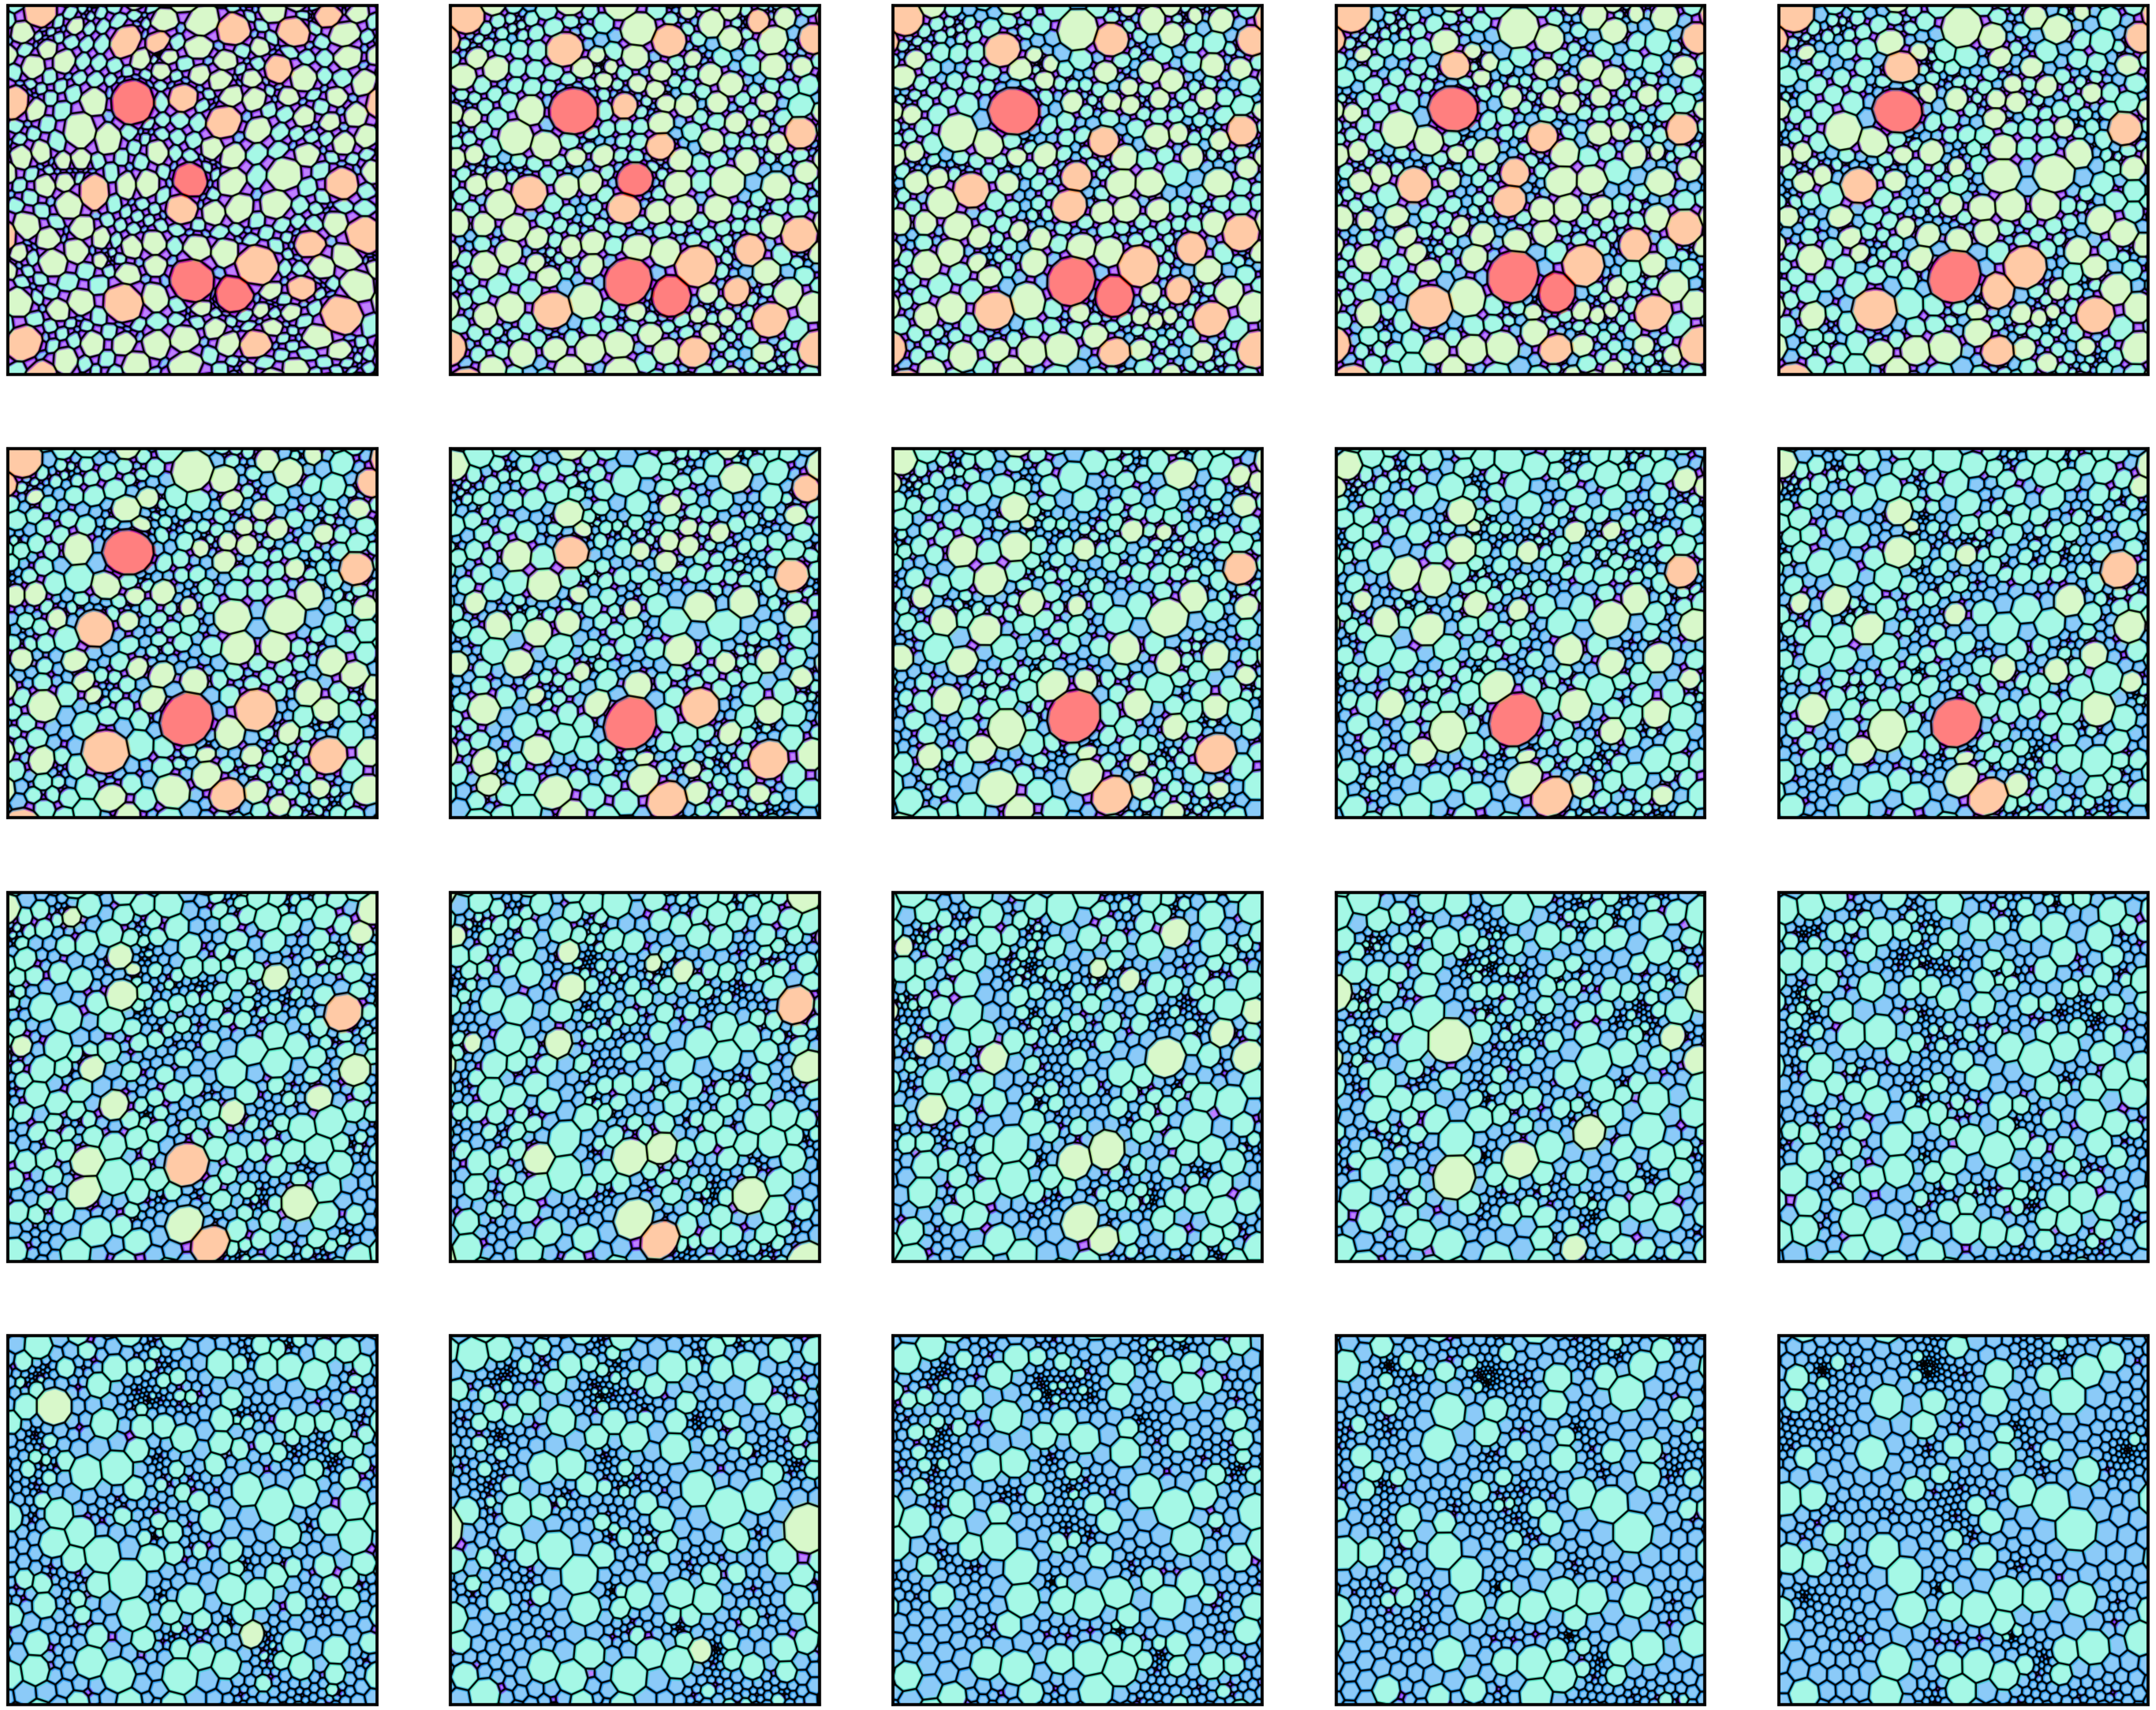
RESULTS O CLOCK

Graphs have 2000 vertices (currently running bigger)

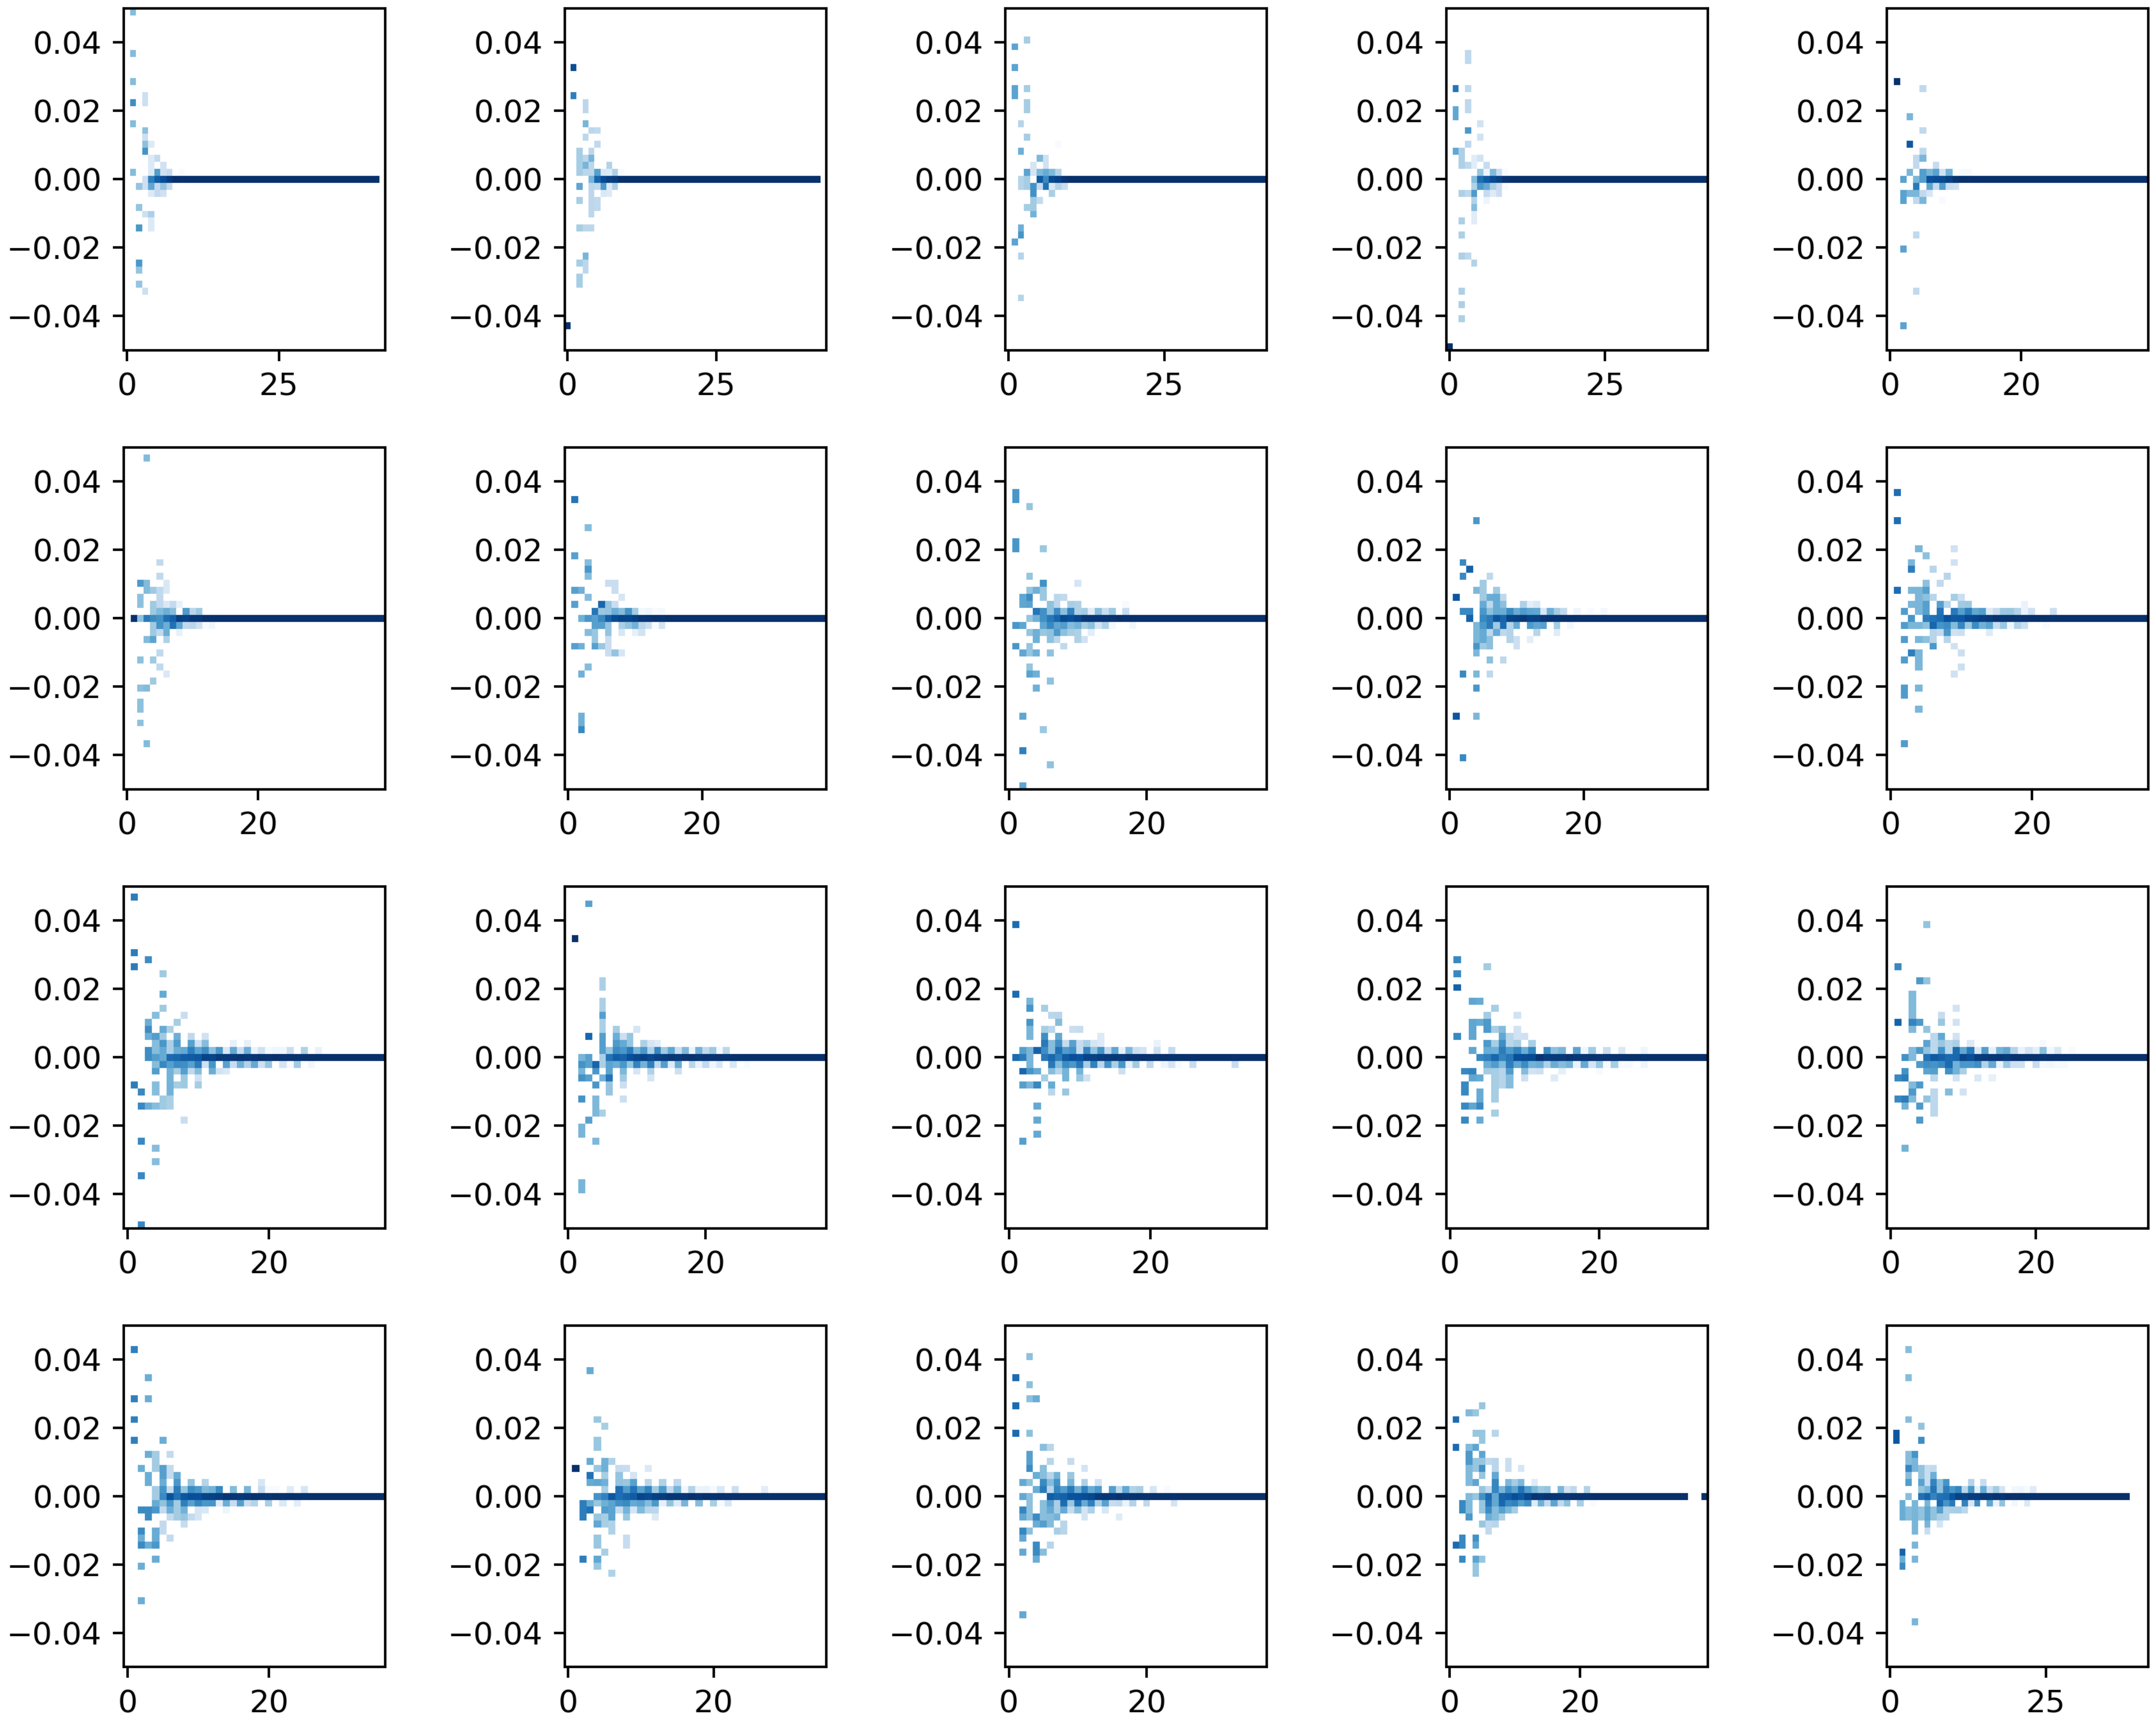


Dimer-dimer correlations decay pretty fast to zero, but i dont think this is the clearest measure

(plots in order of graphs)

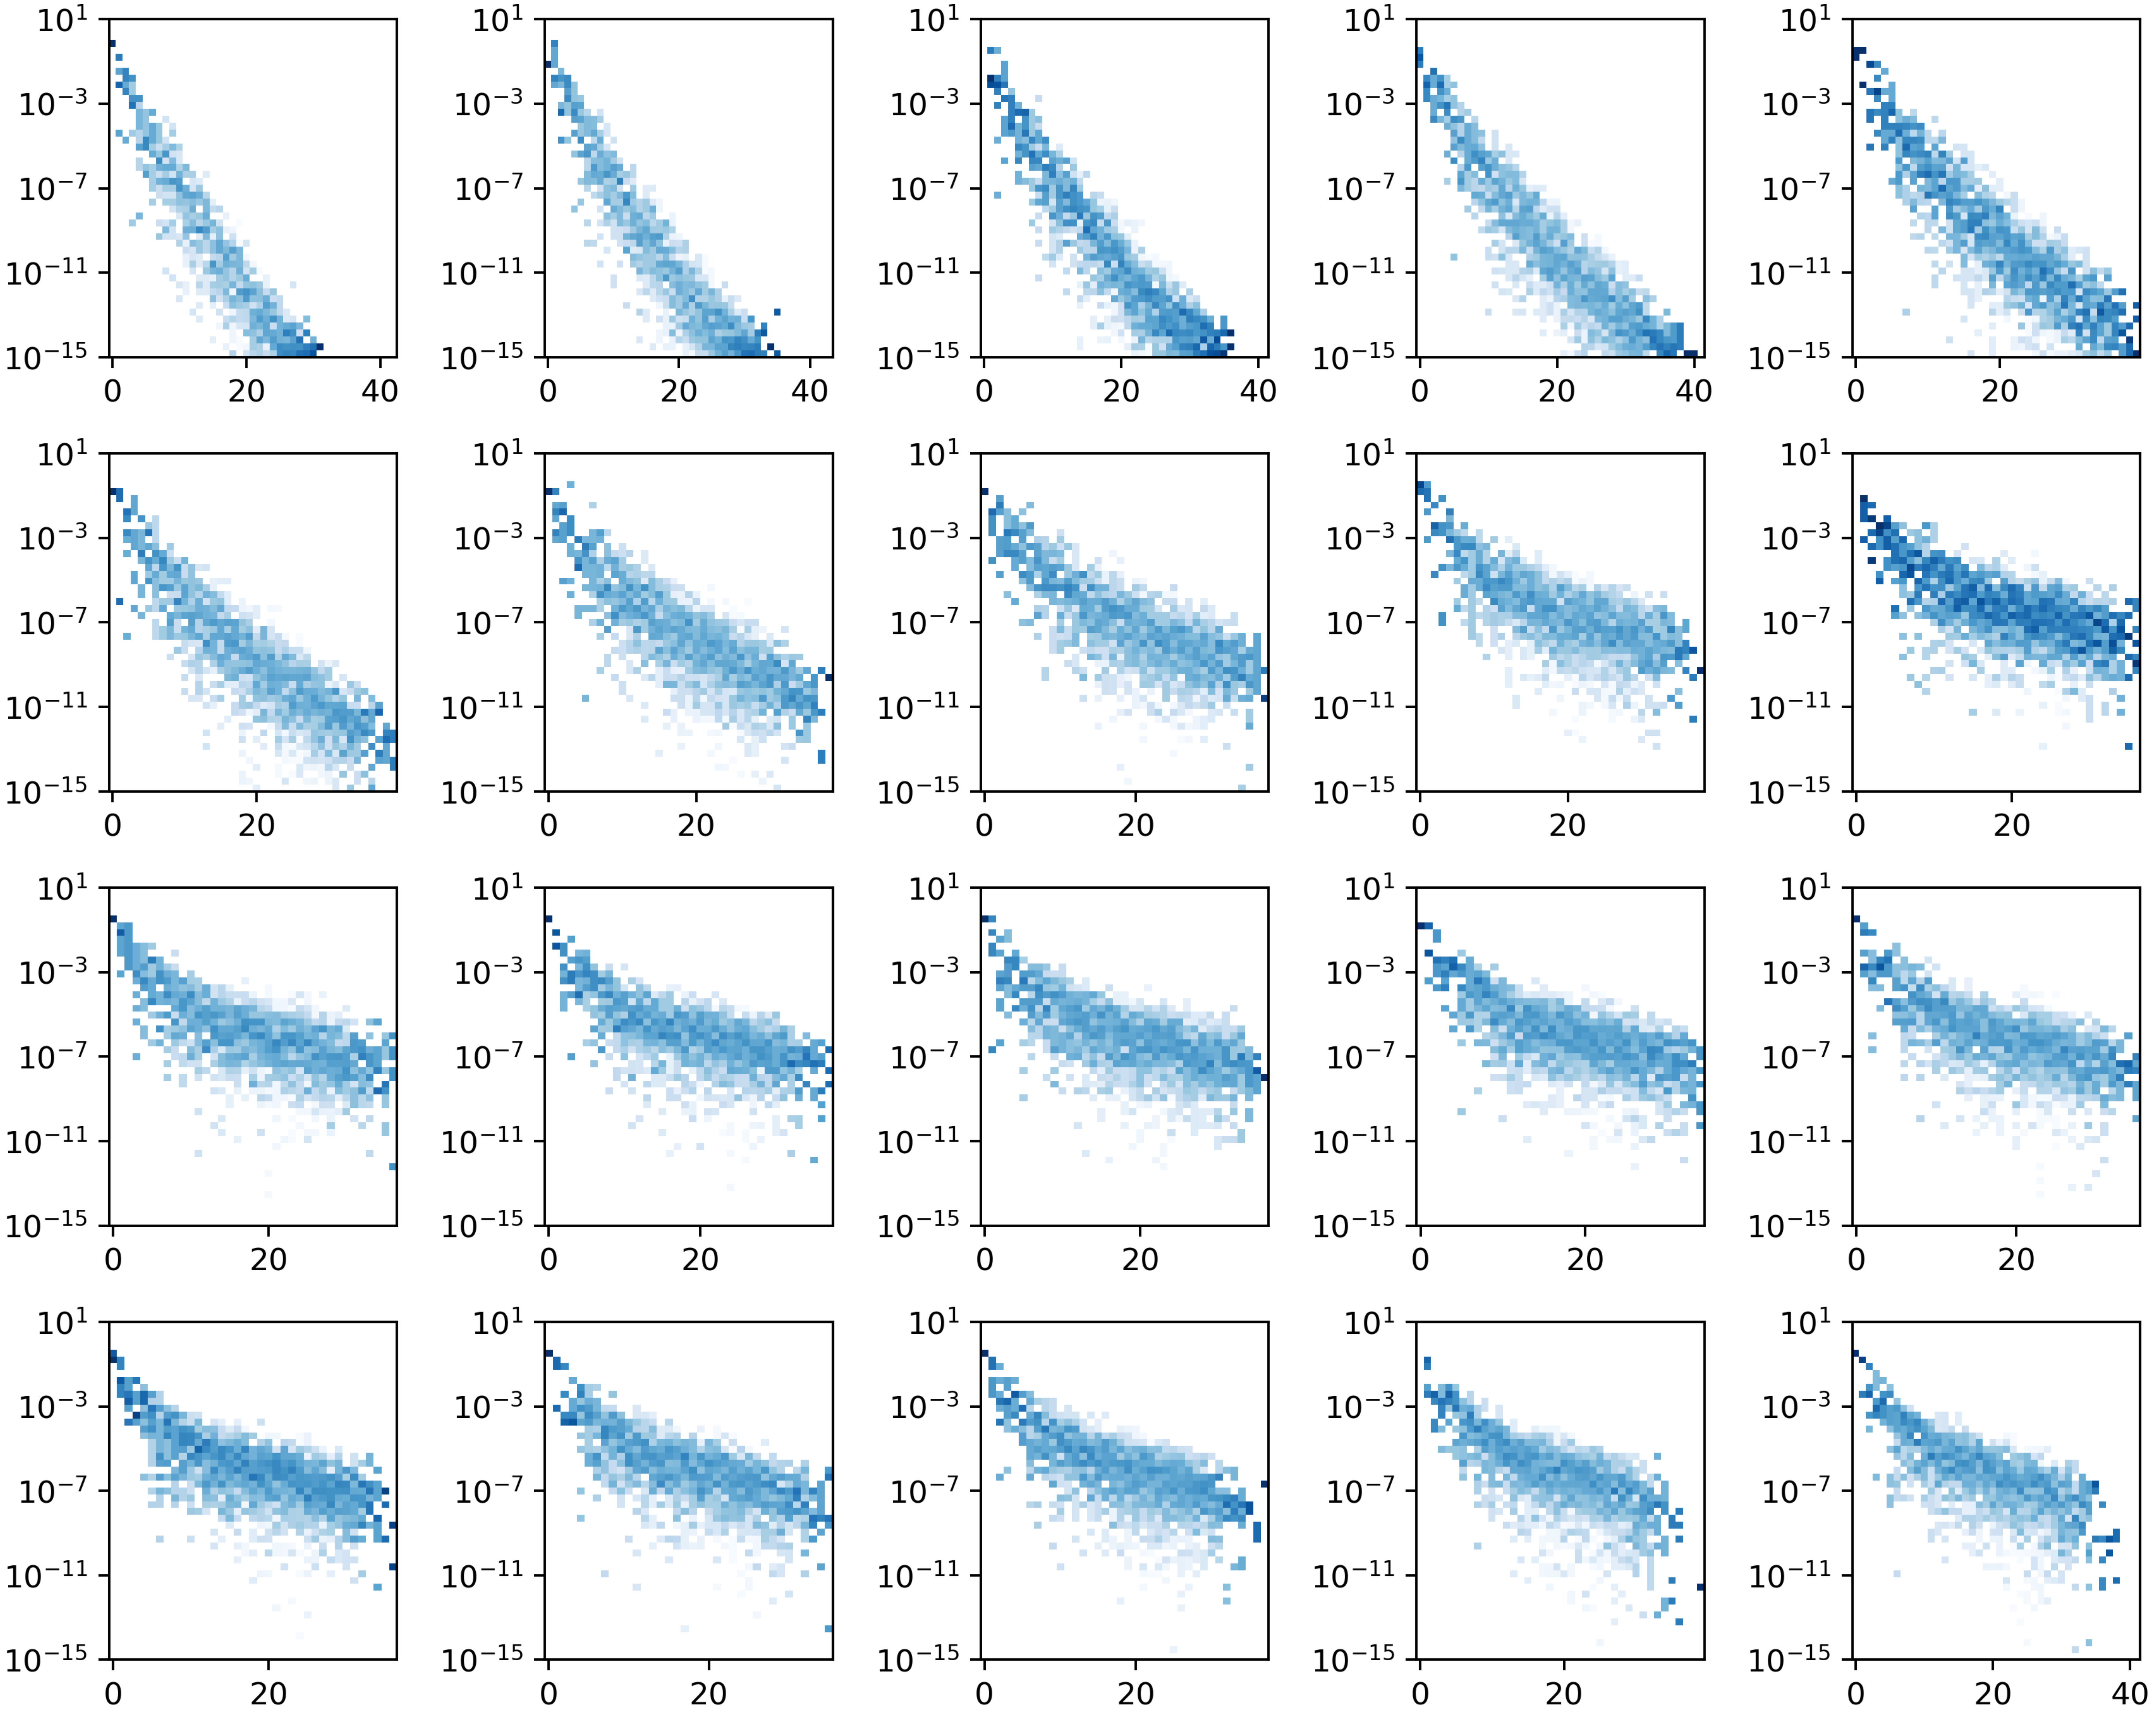
by correlations i mean probability of both edges having dimers minus the prob of each

p(ab) - p(a)p(b)



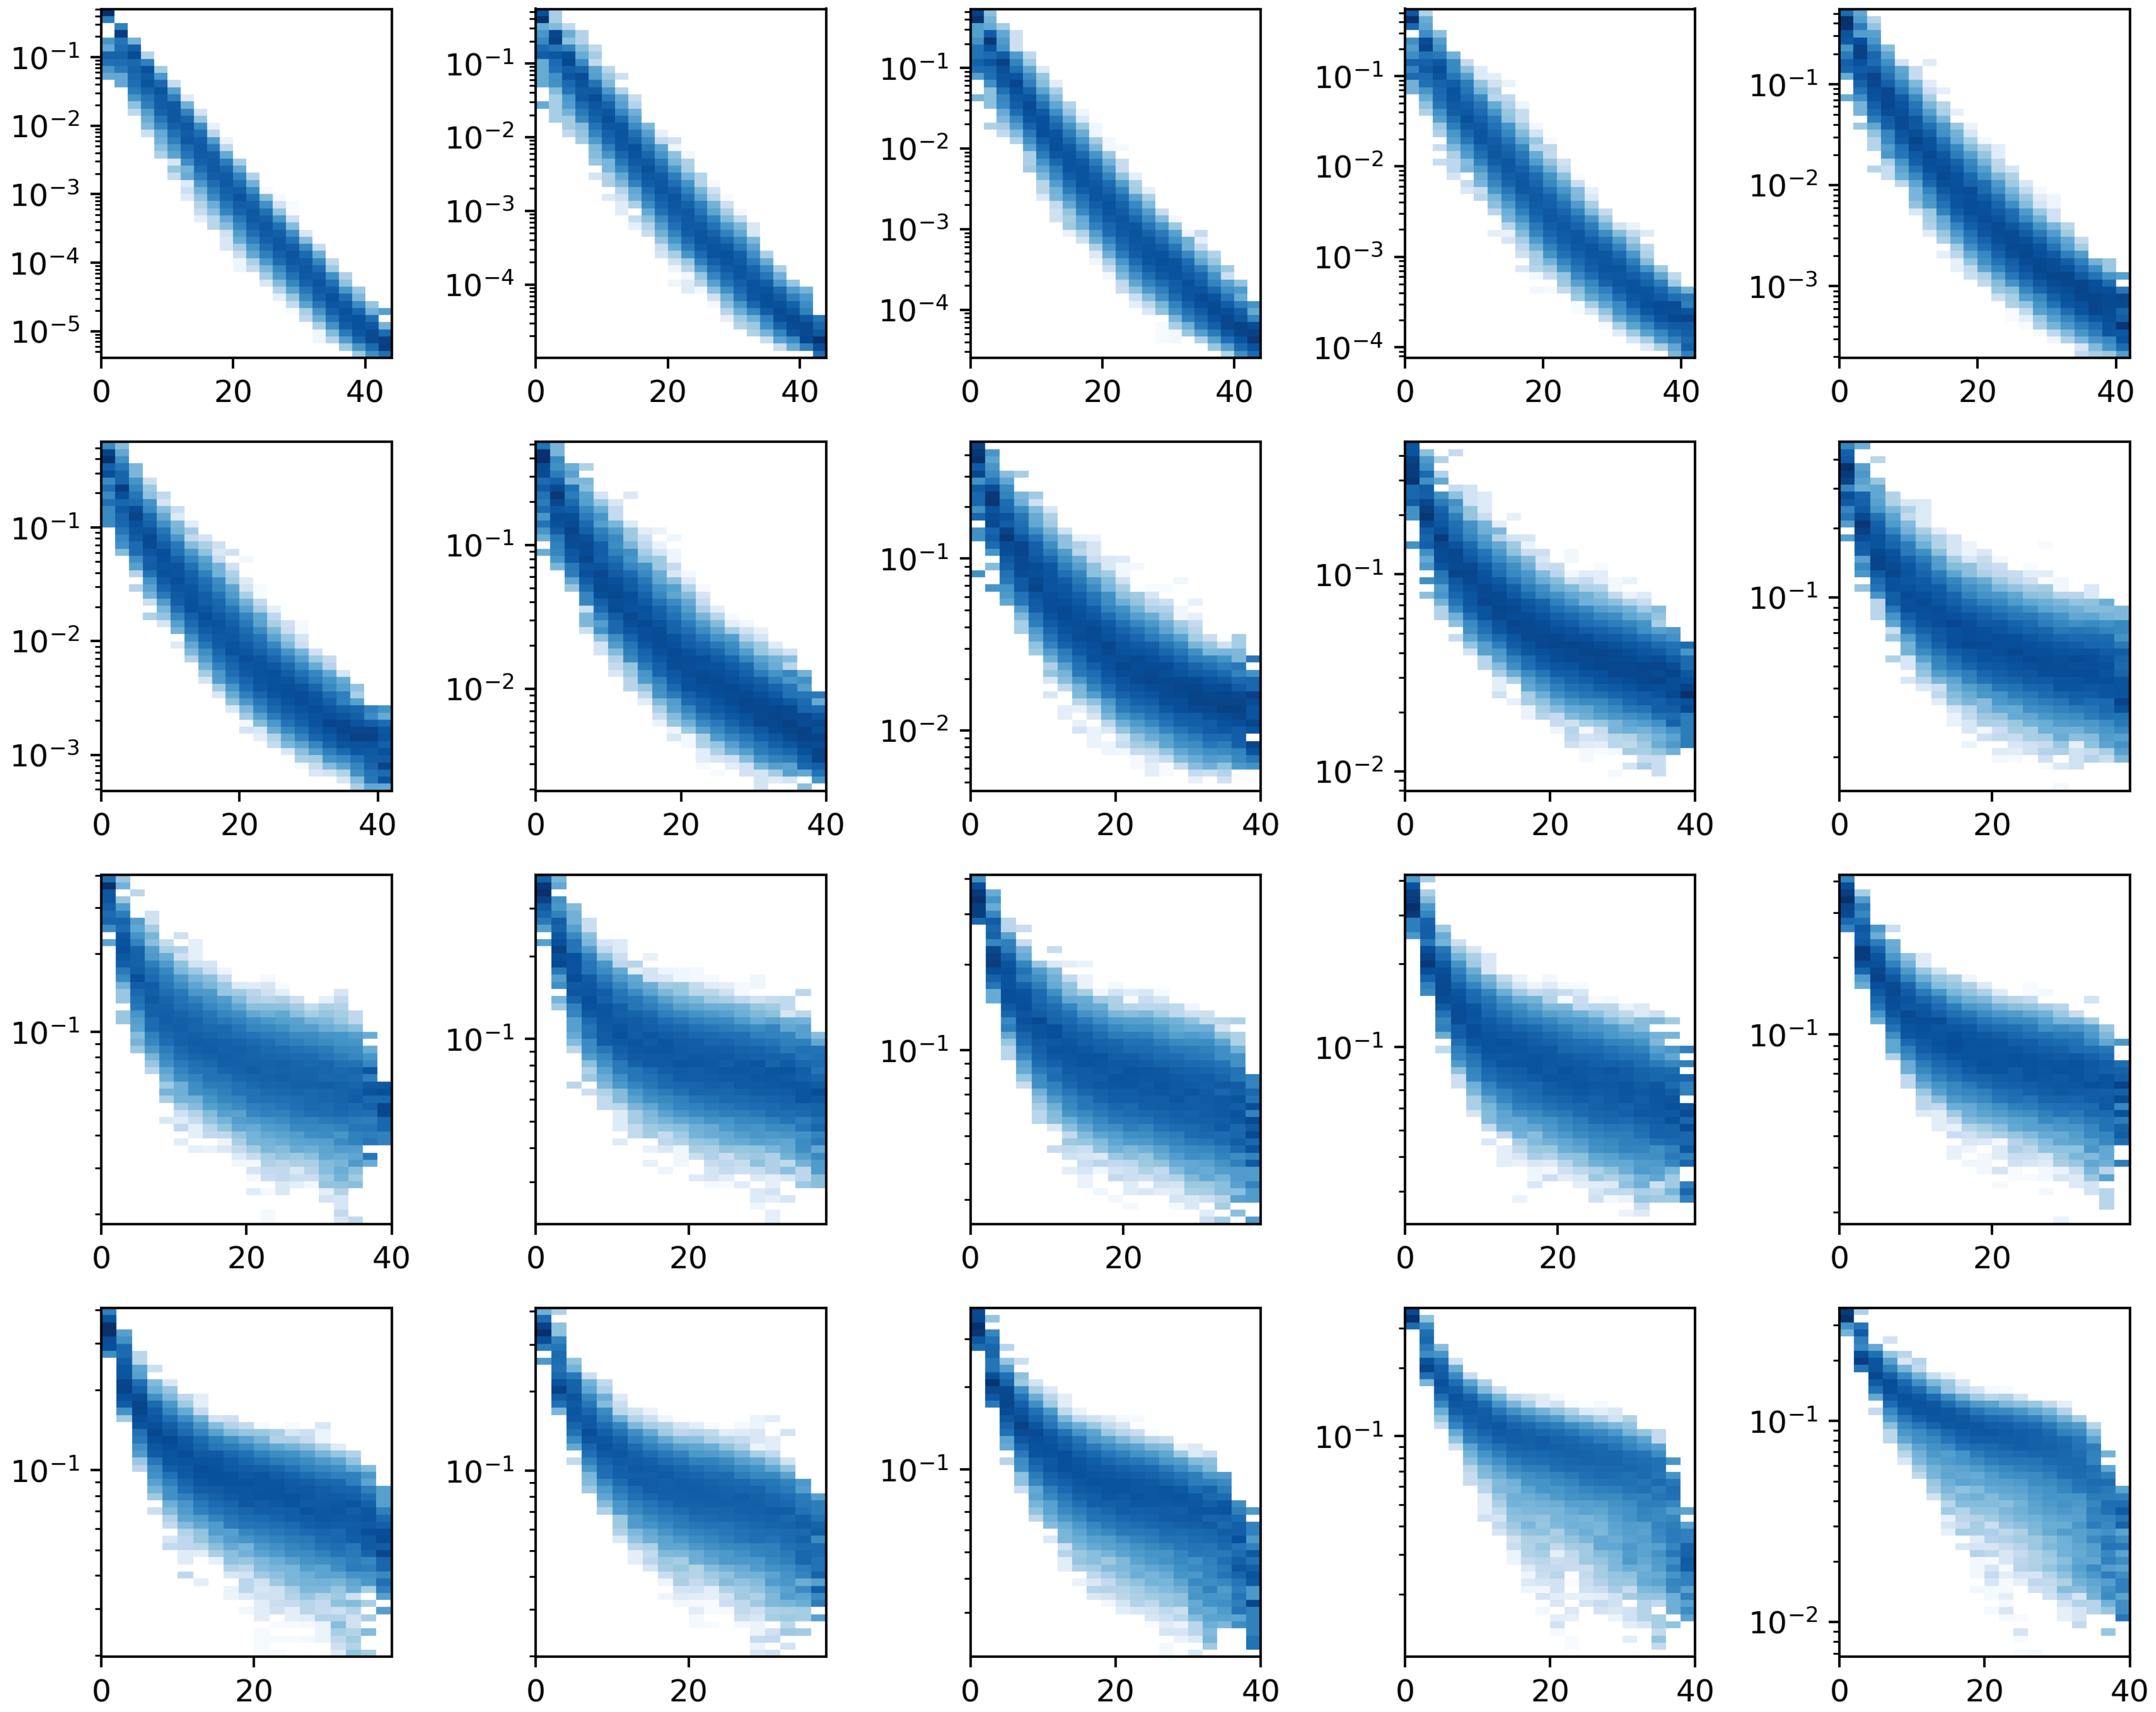
Instead lets look at mutual information between the probability of having a dimer at each site as a function of distance

looks like it goes from exponential to some sort of power law



Monomer correlations also look like they're doing the same exp->power law

question is what function to fit to see this transition?



I dont really know what to make of the vison correlations…

Clearly you can see a splitting in the squoctagon phase, probably depending on whether the vison is in a square or a big plaquette next to a square…

also the squoc correlations dont seem to decay but the mostly honeycomb correlations do…

More data is needed I think, and bigger systems.
